Host-Based Exploit Defenses

• Firewalls: defenses against worms in-network
  – Can see lots of traffic at one monitoring point
  – Can filter traffic for many vulnerable hosts
  – Limited information available: only packet fields, payload contents

• Today: identifying and defending against exploits (and so against worms) on hosts
  – Much more information: see effect of network request on running process’s execution!
  – Potentially more accurate
  – Requires changes to host software
  – Performance concern; don’t want to slow busy server
Outline

• W⊕X page protections
  – and limitations

• Address Space Layout Randomization
  – and limitations

• TaintCheck
  – and limitations
Goals for Host-Based Exploit Defenses

- Works on executables
  - ...and so for legacy code
  - Source code often not available
- Prevents broadest possible range of exploits
- Low/no false positives, false negatives
- Minimal performance reduction
  - Server operator won’t want to sacrifice performance
  - Attacker may recognize server protected if performance slows—and not send malicious request!
• Recall from OS: CPU implements page protection in hardware
  – For each 4K memory page, permission bits specified in page table entry in kernel: read, write

• Central problem in many exploits:
  – Code supplied by user in input data
  – Execution transferred to user’s input data

• **Idea:** don’t let CPU execute instructions stored in data pages
  – i.e., each page should either be writable or executable, but not both: \( W \oplus X \)
  – Text pages: \( X \), not \( W \)
  – Data (stack, heap) pages: \( W \), not \( X \)
W⊕X Details

• Originally no X bit in Intel CPUs; just R and W, all R pages implicitly X
• AMD and Intel introduced “NX” bit (no execute); available on today’s processors (in PAE mode)
  – Not a new idea; present in, e.g., DEC Alpha
  – Used by Linux PaX and Windows XP SP2
• Linux PaX implements W⊕X for x86 processors without NX bit hardware
  – Based on segment limit registers
  – Halves address space available to each process
  – Minor performance reduction
• W⊕X breaks just-in-time (JIT) code generation in legacy applications!
W+X Hole: Return-to-libc Attacks

- Instead of putting shellcode on stack, can put args there, overwrite return address with pointer to well known library function
  - e.g., `system("/bin/sh");`
- Return-to-libc attack
WresultSet: Return-to-libc Attacks

- Instead of putting shellcode on stack, can put args there, overwrite return address with pointer to well known library function
  - e.g.,
    `system("/bin/sh");`
- Return-to-libc attack
W⊕X Hole: Return-to-libc Attacks

• Instead of putting shellcode on stack, can put args there, overwrite return address with pointer to well known library function
  – e.g.,
    `system("/bin/sh");`

• Return-to-libc attack
**W CONTENT** **X Hole: Return-to-libc Attacks**

- Instead of putting shellcode on stack, can put args there, overwrite return address with pointer to well known library function
  - e.g., `system("/bin/sh");`
- Return-to-libc attack
WัยX Hole: Return-to-libc Attacks

- Instead of putting shellcode on stack, can put args there, overwrite return address with pointer to well known library function
  - e.g.,
  ```c
system("/bin/sh");
  ```
- Return-to-libc attack
W+X Hole: Return-to-libc Attacks

- Instead of putting shellcode on stack, can put args there, overwrite return address with pointer to well known library function
  - e.g., `system("/bin/sh");`
- Return-to-libc attack
Address Space Layout Randomization (ASLR)

• Central observation: attacker must predict addresses
  – e.g., shellcode buffer address, libc function address, string argument address

• Idea: randomize addresses in process
  – With high probability, attacker will guess wrong
  – Jump to unmapped memory: crash
  – Jump to invalid instruction stream: crash

• Useful as efficient exploit detector
  – Memory faults or illegal instructions suggest exploit
ASLR Implementation: PaX for Linux

- Linux process contains three memory regions:
  - **Executable**: text, init data, uninit data
  - **Mapped**: heap, dynamic (shared) libraries, thread stacks, shared memory
  - **Stack**: user stack

- ASLR adds random offset to each area when process created
  - Efficient; easily supported by virtual memory hardware
  - 16, 16, 24 bits randomness, respectively

- Mapped offset **limited to 16 bits**
  - bits 28-31 cannot be changed; would interfere with big mmap()s
  - bits 0-11 cannot be randomized; would make mmap()ed pages not be page-aligned
Derandomization Attack on ASLR [Shacham, Boneh et al.]

• 16 bits not that big; try to guess random offset added to mapped area

• Once know random offset, can predict addresses of shared libraries
  – thus libc function addresses
  – ...so can mount return-to-libc attack

• Two phases:
  – brute-force random offset to mapped area
  – compute “derandomized” address of syscall(), use in return-to-libc attack
Derandomization Attack Details

- Target: "classic" stack buffer overflow placed in Apache web server
  ```c
  char buf[64];
  ...
  strcpy(buf, input);
  ```
- Plan:
  - Try to return to usleep(), guessing random offset for mapped area each time
  - If guess wrong, target process crashes, closes connection immediately; parent forks new child (with same random offset)
  - If guess right, target process delays in usleep(), then crashes and closes connection immediately
Derandomization Attack: Phase 1

• Know offset of `usleep()` within libc, know base of mapped area (w/o randomization)

• Each return address guess:
  base + `usleep()` offset + guess in [0, 64K]

• If guess wrong, crash

• If guess right, `usleep()` sees return address 0xdeadbeef, arg 16,843,009 usec (16 sec); sleep, crash
Derandomization Attack: Phase 1

- Know **offset** of `usleep()` within libc, know **base** of mapped area (w/o randomization)
- Each return address guess:
  - `base + usleep() offset + guess in [0, 64K]`
- If guess wrong, crash
- If guess right, `usleep()` sees return address `0xdeadbeef`, arg 16,843,009 usec (16 sec); sleep, crash
Derandomization Attack: Phase 1

- Know **offset** of `usleep()` within libc, know **base** of mapped area (w/o randomization)
- Each return address guess:
  ```plaintext
  base + usleep() offset + guess in [0, 64K]
  ```
- If guess wrong, **crash**
- If guess right, `usleep()` sees return address 0xdeadbeef, arg 16,843,009 usec (16 sec); sleep, **crash**
Derandomization Attack: Phase 1

- Know **offset** of `usleep()` within libc, know **base** of mapped area (w/o randomization)
- Each return address guess: \( \text{base} + \text{usleep()} \text{ offset} + \text{guess in } [0, 64K] \)
- If guess wrong, **crash**
- If guess right, `usleep()` sees return address 0xdeadbeef, arg 16,843,009 usec (16 sec); sleep, **crash**
Derandomization Attack: Phase 1

- Know **offset** of `usleep()` within libc, know **base** of mapped area (w/o randomization)
- Each return address guess: 
  
  base + `usleep()` offset + guess in [0, 64K]
  
- If guess wrong, **crash**
- If guess right, `usleep()` sees return address 0xdeadbeef, arg 16,843,009 usec (16 sec); sleep, **crash**

[Diagram showing memory addresses and function calls]
Derandomization Attack: Phase 1

- Know offset of `usleep()` within libc, know base of mapped area (w/o randomization)
- Each return address guess: \( \text{base} + \text{usleep()} \text{ offset} + \text{guess} \text{ in } [0, 64K] \)
- If guess wrong, crash
- If guess right, `usleep()` sees return address \( 0x\text{deadbeef}, \text{ arg } 16,843,009 \text{ usec (16 sec)}; \text{ sleep, crash} \)
Derandomization Attack: Phase 2

- Now know random offset of mapped area
- Compute **exact address of system() libc function:**
  \[ \text{address} = \text{base} + \text{system()} \text{ offset in libc} + \text{guessed random offset} \]
- Perform **return-to-libc attack using system(), as in earlier example:**
  - “/bin/sh” in buf[] on stack
- Turns out **caller’s frame contains pointer to buf[]!**
- So overwrite stack past buf[] with **several copies of address of any ret instruction found in libc, followed by address of system()**
  - Repeatedly pops stack until returns to system(), with pointer to buf[] on top of stack (argument position)
  - Details in paper, top of p. 8
Derandomization Attack: Performance

- Many trials of phase 1 necessary to learn random offset of mapped area on server
- For 1.8 GHz AMD Athlon server, attacked by 2.4 GHz Pentium 4 client:
  - 216 seconds on average to complete both phases
  - 200 bytes of traffic per probe; 12.8 MB data from client worst-case, 6.4 MB data in expectation
Can ASLR Be Made More Robust?

- 64-bit CPU architectures
  - Probably 40 bits of random offset; much harder to brute-force without attracting attention; so some help with new hardware

- Re-randomize address space after every crash (probe)
  - For single randomization at startup, expected number of probes: $2^{n-1}$
  - For re-randomized n-bit random offset, expected number of probes: $2^n$
  - Only twice as many probes needed as in attack when randomizing once at start!
  - Not promising...
TaintCheck: Detecting Exploits by Analyzing Server Execution

• Approach: instrument program to monitor its own execution, detect when exploit occurs

• Goals:
  – Work on binaries (no source code required)
  – Low false positives/false negatives
  – Detect wide range of exploits (new varieties all the time; point solutions unconvincing)
  – Help humans understand how exploit worked, after the fact; how did data flow from malicious input to point of exploit?
TaintCheck:
Basic Execution Monitoring Idea

• Many exploits use data supplied by user (or derived from data supplied by user) to subvert control flow of program
  – Need to **modify jump, call instruction target addresses, or function return addresses**

• During execution, before any control transfer instruction, **validate target address not derived from user-supplied data**
  – If it is, exploit detected; **raise alarm**
  – If it isn’t, **continue execution normally**
Tainting User Input and Data Derived from It

- User is the source of exploits; don’t trust data from him
- Mark all data from user (received from network, or from input files) as tainted
- Propagate taint during execution
  - Results of operations on tainted data should be tainted
  - Copies of tainted data should be tainted
- Clear taint when tainted data overwritten with untainted data
- How do we get a precompiled program executable to behave this way?
Valgrind: Modifying Executables at Runtime

- Run executable under **Valgrind** system
- Give Valgrind instructions on how to instrument executable
  - literally, *what instructions or function calls to search for, and what instructions to add to them*

- Valgrind’s processing loop:
  - Fetch next basic block of program (dictated by IP/PC)
  - Translate code into UCode, Valgrind’s instruction set
  - Add instrumentation code to Valgrind UCode
  - Translate code back to x86; cache for reuse
  - Execute instrumented x86 basic block
  - Repeat...
Adding Instrumentation: Tracking Tainted Data

• After I/O system calls:
  – If reading from socket, mark target buffer contents as tainted

• After all memory load instructions:
  – If source memory tainted, mark register tainted
  – If source memory untainted, mark register untainted

• After all memory store instructions:
  – If source register tainted, mark memory tainted
  – If source register untainted, mark memory untainted

• After all arithmetic instructions:
  – If any operand tainted, mark result tainted
  – If no operands tainted, mark result untainted
Adding Instrumentation: Detecting Invalid Uses of Tainted Data

- Before all control transfer instructions, add code:
  - If register or memory location holding target function pointer is tainted, raise alarm
  - Means derived from user input; should never happen!
- Needed before each jump, call, ret
Tracking Taint: Shadow Memory

- For every byte of memory, keep shadow memory that tracks taint status
- Simple interface:
  - $\text{Is-Tainted(addr)} \rightarrow \{\text{T} \mid \text{F}\}$
  - $\text{Taint(addr, len)}, \text{Untaint(addr, len)}$
- Two modes of operation
  - Fast: single bit for each byte of memory
  - Detailed: 4-byte pointer to Taint data structure, containing details of system call, stack, value; written at time of tainting
  - Detailed mode useful for analysis of exploits
- Implementation greatly affects performance
  - Space vs. time tradeoff: packed vs. unpacked
Corner Case: Implicit Flows

• Suppose x tainted, then execute:
  
  ```java
  if (x == 0)
      y = 0;
  else
      y = 1;
  ```

• TaintCheck doesn’t taint processor condition flags
  – Would often result in inappropriate propagation of taint; false positives

• But x clearly influences value of y, and y could later influence other values

• Result: false negatives are possible
  – e.g., image compression bit-twiddling code?
Exploit Detection Coverage

- TaintCheck can also instrument function and system calls
- e.g., check printf()-like library calls for tainted format string args
- Built system successfully detects many overwrite exploits (return address, function pointer, format string, GOT entry)
TaintCheck’s Performance: Monitoring Apache

- Lots of extra instructions...
- Exec time not really right metric; throughput better metric
**TaintCheck: Modes of Use (1)**

- **Identify worm payloads**
  - Can be configured to store trace of tainted data flow from all inputs
  - When exploit detected, can walk back to identify input that led to exploit
  - Could pass worm payloads to signature generation system, like Autograph
    - Much more accurate than port-scanner heuristic!

- **Prevent exploit of server**
  - Halt execution upon exploit detection
TaintCheck: Modes of Use (2)

- Probably too slow for production servers
  - 25X server farm size increase for Amazon?
- Could possibly deploy on a few servers: 
  sample traffic
  - Would slow detection of new worm, though; only sampling some inputs
  - Adversary may possibly be able to detect monitored servers by their slow response time; avoid sending them exploit payload
