### Abstract

A between-group experiment was carried out to assess whether two different presence questionnaires can distinguish between real and virtual experiences. One group of 10 subjects searched for a box in a real office environment. A second group of 10 subjects carried out the same task in a virtual environment simulating the same office. Immediately after their experience subjects were given two different presence questionnaires in randomised order: the Witmer and Singer Presence (WS), and the questionnaire developed by Slater, Usoh and Steed (SUS). The paper argues that questionnaires should be able to pass a 'reality test' - whereby under current conditions the presence scores should be higher for real experiences than for virtual ones. Nevertheless, there was only a marginally higher mean presence score for the SUS score for the real compared to the virtual, and no significant difference at all in the case of the WS mean score. It is concluded that though such questionnaires may be useful when all subjects experience the same type of environment, their utility is doubtful for the comparison of experiences across environments - such as immersive virtual compared to real, or desktop compared to immersive virtual.

## 1. Introduction

The concept of presence in a virtual environment (VE) naturally raises the question of the meaning of 'presence' with respect to real world experiences. Let's leave aside here ontological questions about the nature of existence. A normally healthy and able conscious individual acting in a physical environment is fully present in that environment with respect to the meaning of presence in a VE. Consider, for example, the early papers discussing the notion of presence (Held and Durlach, 1992; Loomis, 1992; Sheridan, 1992; Zelter, 1992; Heeter, 1992; Steuer, 1992). A summary of the factors thought to influence presence as introduced in these papers include:

1. High resolution information displayed to the participant, in a manner that does not indicate the existence of the display devices. This includes Steuer's notion of vividness, 'the ability of a technology to produce a sensorially rich mediated environment'.
2. Consistency of the displayed environment across all sensory modalities;
3. The possibility of the individual being able to navigate through and interact with objects in the environment, including interaction with other actors which may spontaneously react to the individual;
4. The individual's virtual body, their self-representation within the environment, should be similar in appearance or functionality to the individual's own body, and respond appropriately to the movements of their head, eyes, and limbs;
5. The connection between individual's actions and effects of those actions should be simple enough for the individual to quickly learn.

Considering each one of these, of course they are at their optimum in the context of a person acting in everyday reality.

Taking into account more recent discussions of presence, Bystrom, Barfield & Hendrix (1999) introduce the Immersion, Presence and Performance model of interaction in VEs. It is implicit in their approach to presence that this would be optimal for people in the real world as compared to a virtual world. Following a quite different perspective Zahoric & Jenison (1998) give a definition of presence as '... tantamount to successfully supported action in the environment.' Their approach

argues that reality is grounded in action rather than in mental filters and that ‘...the reality of experience is defined relative to functionality, rather than to appearances’ (Flach & Holden, 1998). This approach to presence is concerned with action rather than the appearance of how things look and sound. In other words ‘being there’ is the ability to *act* there. It is clear that in this approach also, the greatest *potential* for people to carry out successful action is in the real world. (Whether or not they can actually carry out these actions because of questions of personal ability or power relationships is another matter). A thorough review of the literature on presence can be found in Draper, Kabur & Usher (1998).

If presence is optimal for real-world experiences then methods that attempt to elicit or measure presence should be able to discriminate between experiences that take place in a physical environment and virtual environment. The vast majority of papers that have studied presence use questionnaires for this purpose. We propose that any method for measuring presence, most especially questionnaires, should be subject to a ‘reality test’. In other words they should be used for a group of subjects acting in a real environment, and the results compared with a group of subjects acting in a virtual environment. Other things being equal, a measure passes the ‘reality test’ only if the measured presence is greater for the real environment, under today’s conditions, and for the foreseeable future.

The idea of a sort of ‘Turing test’ for VEs has been proposed in the literature. For example, Steuer (1992) suggested that a methodology for measuring the efficacy of a virtual environment would be the extent to which subjects could not discriminate between it and a real environment. The approach of Schloerb (1995) towards measuring presence is on similar lines. It is implicit in these suggestions, and perhaps so obvious that it is overlooked, that presence should therefore be higher in a real than in a VE, other things being equal.

In this paper we report an experiment which had the sole purpose of subjecting two presence questionnaires to this reality test. The first is a formally proposed and evaluated questionnaire con-

structed by Witmer & Singer (1998). Their Presence Questionnaire consists of 32 questions each on a 1 to 7 scale. Each question corresponds to a factor thought to be correlated with presence, such as, for example: 'How much were you able to control events?' The final presence score is the sum of 32 such questions. We refer to this questionnaire as WS.

The second approach is that developed over a number of studies by Slater and colleagues most recently used in (Slater, Steed, McCarthy & Maringelli, 1998; Usoh, Arthur, Whitton, Bastos, Steed, Slater & Brooks, 1999). This is based on several questions all variations on one of three themes: the sense of being in the VE, the extent to which the VE becomes the dominant reality, and the extent to which the VE is remembered as a 'place'. Suppose in a particular study  $n$  such questions are asked, each on a 1 to 7 scale where the higher score indicates greater presence. The presence score is taken as the number of answers  $r$  out of  $n$  that have a score of '6' or '7'. In particular, if this measure of presence is to be used as a response variable in a regression analysis on a number of explanatory and independent variables, then logistic regression would be employed rather than normal regression. We refer to this questionnaire as SUS (Slater-Usoh- Steed).

## **2. Method**

The study involved 20 people searching for a red box hidden in one of the University research laboratories (called the 'office space' from now on). There were two versions of this space: the real space, and a virtual environment model of this space. (See Figure 1 and Figure 2). The 20 people were recruited by advertisement in the University campus, and assigned randomly to one of two groups. The first group (V) experienced only the virtual office space, and carried out their task of searching for the box, entirely within this VE. The second group (R) carried out the same task in the real office space. All of the subjects were students. In the V group there were 3 females and 7 males, in the R group 2 females and 8 males. The subjects were paid the equivalent of about \$9 US.

The search task took between 7 and 14 minutes for those in the virtual office, and between 6 and 10 minutes for those in the real office. At the end of the search task the subjects answered the two

---

## Using Presence Questionnaires in Reality

questionnaires: WS and SUS. In order to avoid the possibility that the order of answering the questionnaires could make any difference this was randomised: half of the subjects in each group first answered WS and then SUS, and the other half in the reverse order.

Almost all of the questions in the WS questionnaire make sense in relation to a real environment. This questionnaire was used as published in the original article. The SUS questionnaire as used in the above cited most recent studies was employed, the only change being that direct references to an experience within a VE were changed to refer to the 'office space'. Hence the same questionnaire could be used for both V and R groups. The 6 questions relating to presence were as follows:

1. Please rate *your sense of being in the office space*, on the following scale from 1 to 7, where 7 represents your *normal experience of being in a place*.  
*I had a sense of "being there" in the office space:*  
1. Not at all ... 7. Very much.
2. To what extent were there times during the experience when the office space was the reality for you?  
*There were times during the experience when the office space was the reality for me...*  
1. At no time ... 7. Almost all the time.
3. When you think back about your experience, do you think of the office space more as *images that you saw*, or more as *somewhere that you visited*?  
*The office space seems to me to be more like...*  
1. Images that I saw ... 7. Somewhere that I visited.
4. During the time of the experience, which was strongest on the whole, your sense of being in the office space, or of being elsewhere?  
*I had a stronger sense of...*  
1. Being elsewhere ... 7. Being in the office space.
5. Consider your memory of being in the office space. How similar in terms of the *structure of the memory* is this to the structure of the memory of other *places* you have been today? By 'structure of the memory' consider things like the extent to which you have a visual memory of the office space, whether that memory is in colour, the extent to which the memory seems vivid or realistic, its size, location in your imagination, the extent to which it is panoramic in your imagination, and other such *structural* elements.  
*I think of the office space as a place in a way similar to other places that I've been today...*  
1. Not at all ... 7. Very much so.
6. During the time of the experience, did you often think to yourself that you were actually in the office space?

---

## Using Presence Questionnaires in Reality

*During the experience I often thought that I was really standing in the office space...*

1. Not very often ... 7. Very much so.

The scenarios were implemented on an SGI Onyx with twin 196 MHz R10000, Infinite Reality Graphics and 192M main memory. The tracking system has two Polhemus Fastraks, one for the HMD and another for a 5 button 3D mouse. The helmet was a Virtual Research VR4 which has a resolution of 742×230 pixels for each eye, 170,660 color elements and a field-of-view 67 degrees diagonal at 85% overlap.

The total scene consisted of 12564 polygons which ran at a frame rate of no less than 20 Hz in stereo. The latency was approximately 120 ms.

Subjects moved through the environment in gaze direction at constant velocity by pressing a thumb button on the 3D mouse.

### 3. Results

The fundamental result is that neither WS nor SUS distinguished between the real and virtual experiences. The results are shown in Table 1. The column 'SUS Count' shows the mean of the SUS count of '6' or '7' scores amongst the 6 questions. The column 'SUS Mean' uses the mean score across the 6 questions instead. Clearly there are no significant differences between the groups for

---

## Using Presence Questionnaires in Reality

the WS or SUS Mean columns. The order in which the questionnaires were presented likewise made no difference to this result.

**TABLE 1. Means and Standard Deviations of Questionnaire Scores**

Group	WS	SUS Count	SUS Mean
Virtual (n=10)	90.3±14.5	1.0±1.7	3.8±1.3
Real (n=10)	90.6±18.4	2.0±2.0	4.4±1.5

Treating the SUS Count response as binomially distributed for a logistic regression on group, as intended for the SUS approach, there is a significant difference between the groups ( $\chi^2 = 4.511$  on 1 d.f. is significant at 5%). This difference is entirely accounted for by two of the six questions, numbers 3. and 6. Hence there is some marginal evidence that the SUS questionnaire satisfies the reality test, but when the mean results for the individual questions are examined (Table 2) not much confidence can be put in this.

**TABLE 2. Means and Standard Deviations of Responses to the Individual SUS Questions**

Group	Q1	Q2	Q3	Q4	Q5	Q6
Virtual	4.3±1.5	3.6±1.3	2.6±1.6	4.6±1.3	4.4±2.3	3.3±2.2
Real	4.0±2.1	4.0±2.3	4.6±2.2	5.1±1.9	3.7±1.9	5.2±1.6

Consider, for example, question 1. The mean score for those in the real office space group was only 4, in response to a question about a sense of really being in the office space!

The SUS questionnaire had a 'free response' final question:

7. Please write down any further comments that you wish to make about your experience. In particular, what things helped to give you a sense of 'really being' in the office space, and what things acted to 'pull you out' of this?

For those in the virtual group, the responses were as expected for a virtual reality experience. Activity such as bending down and looking underneath tables tended to reinforce the sense of being in the office space. The lag in response to head movements, the lack of collision detection with vir-

---

### Using Presence Questionnaires in Reality

tual objects, and interference from physical cables and bumping into other real objects all tended to bring subjects out of the experience.

Of greater interest are the comments of those in the real office space - for these give some insight into how they interpreted the overall questionnaire. Reasons given for the enhancement of being in the office space were:

1. The office being similar to another one where the subject had previously worked.
2. Sounds such as people talking on the phone.
3. Visual cues such as computers and paper clips.
4. Natural lighting.
5. Other people's reaction to his presence gave a greater sense of being in the office space. 'It made you aware of your own presence in a way'.
6. Being given the task of having to look for something in the office.
7. The layout, the way that the individual desks and PCs were arranged.
8. Heightened sensitivity caused by being in a new environment.
9. 'Only felt very much in the office when someone turned and asked if they could help.'

The reasons given for being pulled out of the office space were:

1. The reactions of 'strangers' in the office space, who did not know the subject nor why she was there.
2. The lack of any smell.
3. The task itself not involving much physical interaction or speech.
4. Being ignored by other people.
5. The fact that not everyone were at their desks and the fact that there was not much noise.
6. Lack of familiarity with the office space.

An interpretation is that those in the virtual office relate their sense of presence more to the system factors - how 'real' is the experience in the sense of the responsiveness of the environment to the individual's actions (e.g., you can really bend down and look underneath objects), but on the other hand there is a delay in response to head movements. Moreover, the real world occasionally intrudes (the cables). For those in the real office, there is also some degree of comparison with an

---

## Using Presence Questionnaires in Reality

other normal or perhaps idealised real environment (visual, auditory and even olfactory issues were mentioned), but also ‘being there’ is at least partially re-interpreted as the degree of *involvement or lack of alienation* in the environment.

There was an interesting relationship between the WS and SUS scores. Figure 3 shows the scatterplot of WS against SUS scores for the group who experienced the virtual office. The correlation was not significant ( $r^2 = 0.22$ ), largely because low SUS scores correspond to a wider range of WS scores. Figure 4 shows the plot for those who experienced the real office. In this case the correlation is significant at 5% ( $r^2 = 0.68$ ). It seems that high SUS scores are consistently associated with high WS scores, but this is not the case for low SUS scores.

Finally, included in the SUS questionnaire was a question relating to task performance:

1. Overall, how well do you think that you achieved your task?  
*I achieved my task...*  
1. Not very well at all ... 7. Very well.

This was uncorrelated with both SUS and WS scores for each of the real and virtual environments. Moreover, each person’s time to completion was recorded, and again this was uncorrelated with the presence scores.

## 4. Conclusions

This paper has suggested a reality test for questionnaires designed to measure presence. The test is that the questionnaire should be applied to individuals in a real environment, and should consistently result in higher ‘presence’ responses than for people in a virtual environment, other things being equal. This test was applied to two presence questionnaires. The Witmer and Singer questionnaire showed no significant differences in measured presence between a group carrying out a

---

## Using Presence Questionnaires in Reality

search task in a virtual environment, and another group carrying out the task in a corresponding real environment. The Slater-Usuh-Steed questionnaire did show a small statistically significant difference between the real and virtual results in the expected direction, although all but two of the individual components of the questionnaire showed no difference. Problems of instability in subjective questionnaires for presence have been recently discussed by Freeman, Avons, Pearson & IJsselstijn (1999), though from quite a different viewpoint, examining the influence of prior experience.

The most important result is that if a scientist asks a lay person a question, for example, concerning their 'sense of being there' that person will come up with some interpretation that makes the question seem sensible, and then answer that question. If someone is asked for their sense of 'being there' on a 1 to 7 scale, it gives them permission to answer with a score of less than 7 even when they are really there. The questions are reinterpreted to make sense in the given context. In a VE presence is interpreted as the sense of being in the environment that is depicted by the computer generated displays, and the ability to act in that environment. In the real-world, since there is no doubt that the individual is present in the obvious sense, it becomes reinterpreted as the sense of involvement, the lack of isolation, perhaps the degree of comfort. The thought 'I am not comfortable to be here' might lead to a low 'presence' response.

We speculate that subjects in an experiment will 'relativise' their responses to presence questions to the domain of their given experimental experiences only. For example, it was recently found that amongst 30 subjects all experiencing the same shared VE, that those who used an immersive head-tracked head-mounted display system did not report a higher overall sense of presence than those using a desktop system, using a variant of the SUS questionnaire (Slater, M., Sadagic, A., Usuh, M., Schroeder, R. (2000) Small Group Behaviour in Virtual and Real Environments: A Comparative Study, *Presence: Teleoperators and Virtual Environments*, 9(1), 37-51. Slater, M., Sadagic, A., Usuh, M., Schroeder, R. (2000) Small Group Behaviour in Virtual and Real Environments: A Comparative Study, *Presence: Teleoperators and Virtual Environments*, 9(1), 37-51.). On the other hand when all subjects experience the same type of immersion, then there are consistent variations of

presence with other control factors such as an interaction technique (Usoh, Arthur, Whitton, Bastos, Steed, Slater & Brooks, 1999). The problem is 'cross-environment' comparisons (virtual to real, immersive to desktop), which do not seem to be valid using this approach.
